

## ⌚ Subclinical Interstitial Lung Abnormalities: Lumping and Splitting Revisited

Identifying patients with idiopathic pulmonary fibrosis (IPF) at the earliest opportunity remains one of the most urgent challenges for the effective management of this deadly disease. A theoretical basis for early IPF detection comes from large lung cancer and cardiovascular cohort studies that have reported shared clinical associations between incidentally detected subclinical interstitial lung abnormalities (ILAs) on computed tomography (CT) and IPF (1). ILAs are more prevalent with increasing age (2–4), in smokers (1, 5, 6), and in patients over the age of 50 who exhibit MUC5B promoter polymorphism positivity (4). ILAs are also associated with a reduction in pulmonary function (1, 5) and exercise capacity (7). Importantly, patients with progressive ILAs demonstrate greater serial pulmonary function decline when compared with patients with stable ILAs (8). However, the consistent observation that ILA prevalence exceeds that of IPF by more than an order of magnitude means that refinement of current ILA definitions and identification of progressive ILA subtypes are critical if screening for early IPF is to be successful (1).

In this issue of the *Journal*, Putman and colleagues (pp. 175–183) extend their impressive portfolio of ILA studies by evaluating the impact of specific ILA features on ILA progression as judged by follow-up CT in a population of adults from the AGES-Reykjavik (Age, Gene/Environment Susceptibility–Reykjavik) study (9). This study is important because it represents the first attempt to identify specific CT features and radiologic patterns linked to the progressive ILA phenotype. ILAs defined as subpleural and reticular, those associated with traction bronchiectasis, and ILAs with a lower-lobe predilection were associated with a greater than sixfold likelihood of progression. Moreover, in 16 patients with ILAs characterized by honeycombing, all five who had follow-up imaging had progressed. The authors also generated a “definite fibrosis” score by amalgamating traction bronchiectasis and honeycombing, which was associated with a greater than eightfold likelihood of progression. Finally, previously reported clinical associations with ILA progression, including increasing age and MUC5B promoter polymorphism positivity, were confirmed.

The importance of standardizing ILA definitions cannot be overstated, and the authors make a considerable effort to maintain consistency and clarity in this regard. However, two issues warrant consideration. First, the separation of fibrotic from nonfibrotic ILA is crucial but challenging in limited or early disease because CT-

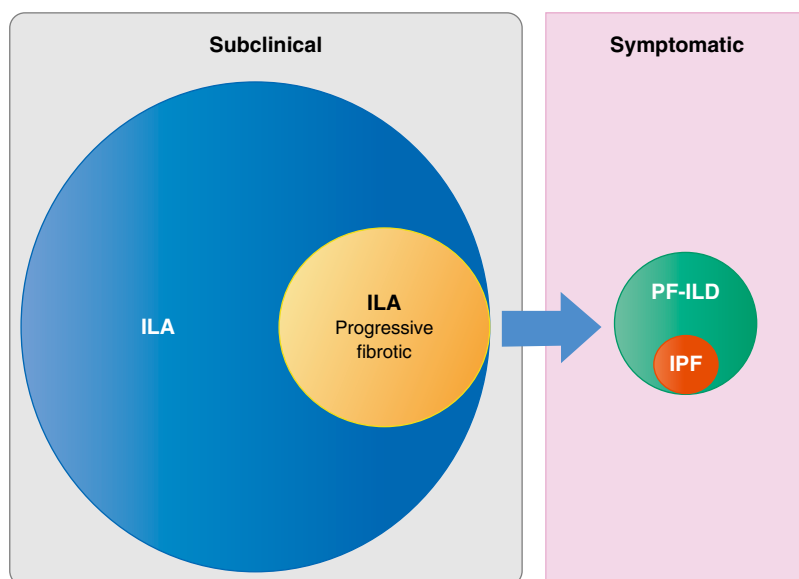

histologic correlation in this setting is imperfect. In one patient, limited subpleural reticulation may be the sole CT manifestation of advanced fibrosis histologically, but in another patient it may not represent fibrosis at all (10). The authors attempt to address this issue by combining traction bronchiectasis and honeycombing, two reliable CT signs of fibrosis, as one variable (“definite fibrosis”), but this is likely to miss at least some cases of reticular ILA representing real fibrotic disease. It is interesting to note that the latest iteration of the international evidence-based joint clinical practice guideline for IPF diagnosis includes in its definition of “indeterminate” for usual interstitial pneumonia (UIP) on CT “subtle reticulation,” which is also described as an “early UIP” pattern (11). In the study by Putman and colleagues, the prevalence of reticular ILA is more than 80%, but only 34% of these cases were considered to represent “definite fibrosis” (9).

The second, related issue is that if “definite fibrosis” is confined to ILAs in which traction bronchiectasis or honeycombing is present, what defines the boundary between this subtype of fibrotic ILA and the presence of established fibrotic lung disease? In the study by Putman and colleagues, patients whose pattern of ILA met guideline criteria for “probable” or “definite” UIP were included in the analysis and, as expected, all of these patients progressed. Furthermore, 89%/100% of those with a “probable”/“definite” UIP pattern, respectively, died at the end of the follow-up period. The inclusion of these patients raises questions regarding the overarching definition of ILA: “imaging abnormalities on chest CT in research participants without a clinical diagnosis of interstitial lung disease.” Based on current guidelines, the majority of these patients would meet diagnostic criteria for IPF (11). Although there is currently no evidence showing that a UIP pattern on chest CT predicts outcome in research participants who have not received a diagnosis, our understanding of UIP as the prototypic progressive radiologic phenotype is supported by a large body of evidence across idiopathic and nonidiopathic fibrotic lung disease cohorts (12–15). If a screening strategy for detecting early IPF is to be successful, we should probably focus our efforts on determining which of the ILAs that are currently considered nonspecific represent early and clinically relevant progressive fibrotic lung disease (Figure 1).

Undoubtedly, a set of standard definitions that would allow consistent ILA reporting and harmonization of cohorts to power larger studies is urgently required. How these definitions should be devised is less clear. Taxonomy can be a double-edged sword that, when wielded indiscriminately, merely replaces understanding with filing—the crux of the well-known “lumping and splitting” debate. Categories that are too rigorously defined lead to distinctions without a difference or impracticable precision, particularly when knowledge is incomplete. Overlapping ILA patterns may exist that by definition cannot be easily placed within a single category. ILA distribution in three dimensions is also likely to be significant based on our

**Figure 1.** Progressive fibrotic interstitial lung abnormalities (ILAs) represent a subtype of ILAs that progress to symptomatic progressive fibrotic interstitial lung disease (PF-ILD), of which idiopathic pulmonary fibrosis (IPF) is one form. The challenge is to determine with accuracy which forms of ILA belong to the progressive fibrotic ILA subtype.

knowledge of ILD, but it can be notoriously difficult to classify visually. Finally, pattern recognition on CT is liable to substantial interobserver variability even among experts (16, 17). Thoracic radiologists have difficulties agreeing on a radiologic diagnosis when an established fibrotic lung disease is present; how agreement on ILA definitions will be impacted when the abnormalities are sparse or poorly defined is anyone's guess. In the current study, the authors report a concordance rate of 81% for the categorization of ILA as present, indeterminate, or absent, but the concordance regarding the classification of ILA subtypes is not clear.

These issues raise tantalizing possibilities for the application of computational image analysis to ILA classification. Over the past decade, there has been a surge in quantitative CT (QCT) research in the ILD setting. Quantitative CT can detect subtle disease progression and prognostic imaging features that elude human assessment (18, 19). These benefits, combined with computer objectivity, are making imaging biomarker exploration in fibrotic lung disease based on visual scoring outdated. More advanced machine-learning methods, and in particular deep learning-based image analysis, will undoubtedly enable further progress in this field, particularly in the domain of new knowledge generation (20, 21). Deep learning is particularly suited to discovering intricate patterns in high-dimensional data, such as images, and mapping them to simple but objective classifications, such as disease progression and mortality. When applied to an appropriately sized cohort, this technology has the potential to facilitate the discovery of radiologic phenotypes representing subclinical fibrotic lung disease that encompass pattern, distribution, and any other predictive CT parameter, including ones imperceptible to human observers. These radiologic phenotypes could be combined with digital lung sound signatures or serum biomarkers to further improve detection of subclinical fibrotic lung disease (22, 23). In the context of the unmet clinical need represented by subclinical IPF detection, the

application of computer-based image analysis is undoubtedly a compelling next step. ■

## ⌚ A Long Noncoding RNA links TGF- $\beta$ Signaling in Lung Fibrosis

Pulmonary fibrosis is an increasing cause of morbidity and mortality worldwide with limited therapeutic options. Idiopathic pulmonary fibrosis (IPF) is a particularly severe form of lung fibrosis, with no known etiology and a median survival of 2.5–3.5 years after diagnosis (1). The pathogenesis of IPF is complex and involves loss of epithelial integrity and excessive fibroblast activation (1, 2).

The TGF- $\beta$  (transforming growth factor  $\beta$ ) signaling pathway plays a central role in the initiation and progression of tissue fibrosis (3). Strategies to target the TGF- $\beta$  signaling pathway have been extensively investigated in preclinical settings (4) and in clinical trials for patients with IPF. Owing to the pleiotropic nature of TGF- $\beta$ , directly blocking TGF- $\beta$  signaling may have adverse

effects. Alternative strategies, such as partial inhibition of TGF- $\beta$  using  $\alpha$ v $\beta$ 6 integrin antibodies, have been investigated (5).

In addition to protein-coding RNAs, many noncoding RNAs (ncRNAs), including microRNAs (miRNAs) and long ncRNAs (lncRNAs), have been recently described. miRNAs are short (~22 nt in length), single-stranded ncRNAs that inhibit the production of target proteins or induce the degradation of mRNAs, thereby suppressing target gene expression. Dysregulation of miRNAs has been shown in the lungs of patients with IPF (6), as well as in animal models of lung fibrosis (7). The roles of miRNAs in lung fibrosis have been studied in humans and in mice (8, 9). lncRNAs are RNA transcripts that are more than 200 nt long and may play a role in gene transcriptional regulation, post-transcriptional regulation, and epigenetic regulation in development and diseases (10).

In this issue of the *Journal*, Savary and colleagues (pp. 184–198) report that the lncRNA *DNM3OS* (DNM3 opposite strand/antisense RNA) serves as an miRNA reservoir in TGF- $\beta$  signaling (11). Using RNA sequencing and small RNA sequencing in a human lung fibroblast cell line (MRC-5) stimulated with TGF- $\beta$ 1, the authors found that the lncRNA *DNM3OS* was one of the most strongly induced lncRNAs. Fluorescent *in situ* hybridization
